**NAME: SHEIKH SUHAIL**

Problem Statement – Design and implement an error detection module.

Design and implement an error detection module which has four schemes namely LRC, VRC, Checksum and CRC. The Sender program should accept the name of a test file (contains a sequence of 0,1) from the command line. Then it will prepare the data frame (decide the size of the frame) from the input. Based on the schemes, codeword will be prepared. Sender will send the codeword to the Receiver. Receiver will extract the dataword from codeword and show if there is any error detected. Test the same program to produce a PASS/FAIL result for following cases.

(a) Error is detected by all four schemes. Use a suitable CRC polynomial (b) Error is detected by checksum but not by CRC.
(c) Error is detected by VRC but not by CRC.

DESIGN

While a bit is travelled from one node to another through the medium it suffers from some electromagnetic interference due to which the data may be prone to the errors like somewhere in the packet of data a bit value may be changed from 1 to 0 or vice versa to detect those errors and find the best way to correct these errors we have some methods which we will discuss in this assignment:

In this assignment, we shall discuss the following error detection techniques in detail.

1. **Vertical Redundancy check**
2. **Longitudinal Redundancy check**
3. **Checksum**
4. **Cyclic Redundancy check**

Vertical Redundancy Check (VRC): This error detection scheme is quite popular in telecommunications and computer networking. This scheme works as follows: the message to be transmitted is split into nibbles (4 bits) and with each nibble a parity bit is associated before data transmission. Note that with even parity bit scheme, the number of 1's in the nibble including the parity bit must be even. For example, for the message **1 0 0 1 0 0 0 1 1 1 0 1** with even parity bit scheme, the message to be transmitted is **100100011 1010**

Longitudinal Redundancy Check (LRC): In contrast to VRC, LRC assigns a parity byte (nibble) along with the message to be transmitted. Suppose the message to be transmitted is 1011, 1000 ,1000 Then, we compute the even parity nibble as follows:

<div align="center">

1011

1000

1000

Parity nibble: 1011

</div>

Checksum: This scheme is a peculiar one wherein we perform 1's complement arithmetic on the data to be transmitted. For the message 1 0 1 1 1 0 0 0 1 0 0 1 , we compute checksum in two steps. The first step performs 1's complement addition on the data and the second step performs the complement on the result of Step 1. The result of Step 2 is the checksum which would be augmented along with the data to be transmitted.

Step 1: Perform 1's complement addition

$$1011$$
$$1000$$
$$\underline{1001}$$
$$\underline{1100}$$
$$\underline{\qquad 1}\text{ (carry from the addition)}$$
$$1101$$

Step 2: Compute Checksum which is the 1's complement of the result of addition.

For the above example the checksum is 0 0 1 0. Along with the message, we append the checksum of the message, i.e., the message to be transmitted is 1011100010010010

At the receiver, we perform 1's complement addition on the received data (message plus checksum), if the result is 1 1 1 1, then the receiver declares that there is no error in the transmission. Otherwise, it declares that there is an error in the transmission.

Cyclic Redundancy Check (CRC): CRC performs mod 2 arithmetic (exclusive-OR) on the message using a divisor polynomial. Firstly, the message to be transmitted is appended with CRC bits and the number of such bits is the degree of the divisor polynomial. The divisor polynomial 1 1 0 1 corresponds to the $x^3 + x^2 + 1$. For example, for the message 1 0 0 1 0 0 with the divisor polynomial 1 1 0 1, the message after appending CRC bits is 1 0 0 1 0 0 0 0 0. We compute CRC on the modified message M.

ANALYSIS OF ERROR DETECTION TECHNIQUES

Vertical Redundancy Check (VRC):

1. This scheme detects all single bit errors. Further, it detects all multiple errors as long as the number of bits corrupted is odd (referred to as odd bit errors). Suppose the message to be transmitted is

10111   10001   10010   and the message received at the receiver is

100*11 10001   10010

2. 0* represents that this bit has suffered from error. For the above example, when the receiver performs the parity check, it detects that there was an error in the first nibble during transmission as there is a mismatch between the parity bit and the data in the nibble. However, the receiver does not know which bit in that nibble is in error. Similarly, the following error is also detected by the receiver.

The message transmitted is

10111   10001   10010

and the message received at the receiver is

0*1*1 1 1   1 0 0 1*1   1 0 0 1 0

Three bits are corrupted by the transmission medium and this is detected by the receiver as there is a mismatch between the 2nd nibble and the 2nd parity bit. It is important to note that the error in the first nibble is unnoticed as there is no mismatch between the data and the parity bit.

3. The above example also suggests that not all even bit erros (multiple bit error with the number of bits corrupted even) are detected by this scheme. If even bit error is such that the even number of bits are corrupted in each nibble, then such error is unnoticed at the receiver. However, if even bit is such that at least one of the nibble has odd number of bits in error, then such error is detected by VRC.

Longitudinal Redundancy Check (LRC):

1. Similar to VRC, LRC detects all single bit and odd bit errors. Some even bit errors are detected and the rest is unnoticed by the receiver.
2. The following error is detected by LRC but not by VRC. For the message 1011 1000 1001, supoose the received message is

   1101 1000 1001 1010
3. In the above example, there is mismatch between the number of 1's and the parity bit in Columns 2 and 3.
4. The following error is detected by VRC but not by LRC. For the message 1011 1000 1001, suppose the received message is
   1 1 0 0* 1 0 0 1* 1001 1010

The above error is unnoticed by the receiver if we follow VRC scheme whereas it is detected by LRC as illustrated below.

1 0 1 0*1 1 0 0 1*1 1 0 0 1 0

5. Here again, not all even bit errors are detected by this scheme. If the error is such that each column has even number of bits in error, then such error is undetected. However, if the distribution is such that at least one column contains an odd number of bits in error, then such errors are always detected at the receiver.

Checksum:

1. If multiple bit error is such that in each column, a bit '0' is flipped to bit '1', then such an error is undetected by this scheme. Essentially, the message received at the receiver has lost the value 1 1 1 1 1 with respect to the sum. Although, it loses this value, this error is unnoticed at the receiver.
2. Also, multiple bit error is such that the difference between the sum of the sender's data and the sum of receiver's data is 1 1 1 1, then this error is unnoticed by the receiver.
3. The above two errors are undetected by the receiver due to the following interesting observations.

4. For any binary data a such that a!=0000, the value of a+(1111) in 1's complement arithmetic is a. On the similar line, if a1,...,an are nibbles, then a1+...+ak+(1 1 1 1) = a1+...+ak This is true because, a + 1 1 1 1 gives a − 1 with a carry '1' and inturn this '1' is added with a − 1 as part of 1's complement addition, yielding a.

5. Consider the scenario in which the sender transmits a1,...,ak along with the checksum and the transmission line corrupts multiple bits due to which we lose 1 1 1 1 on the sum. Although, the receiver received a1+...+ak-(1 1 1 1), it follows from the above observation that a1+...+ak-(1 1 1 1) is still a1+...+ak, thus error is undetected.

6. Similar to other error detection schemes, checksum detects all odd bit errors and most of even bit errors.

Cyclic Redundancy Check (CRC):

1. The answer to whether CRC detects all errors depends on the divisor polynomial used as a part of CRC computation. Consider the divisor polynomial x^2 which corresponds to 1 0 0 and the message to be transmitted is 1 0 1 0 1 0. After appending CRC bits (in this case 0 0) we get 1 0 1 0 1 0 0 0. Assuming during the data transmission, the 3rd bit is in error and the message received at the receiver is 1 0 1 0 1 1*0 0. On performing CRC check on 1 0 1 0 1 1 0 0, we see that the remainder is zero and the receiver wrongly concludes that there is no error in transmission. The reason this error is undetected by the receiver is that the message received is perfectly divisible by the divisor 1 0 0. More appropriately, if we visualize the received message as the xor of the original message and the error polynomial, then we see that the error polynomial is divisible by 1 0 0.

2. Messagereceived=10101100
   Message received = message transmitted + error polynomial, i.e.,
   10101100=10101000+00000100
   Clearly both are divisible by the divisor 1 0 0. In general, if the error polynomial is divisible by the divisor, then such errors are undetected by the receiver. The receiver wrongly concludes that there is no error in

transmission. For example, if the error polynomial is 0 0 0 0 1 1 0 0 (3rd and 4th bits in the message in error), then the receiver is unaware of this error.

3. However, if the divisor is 1 0 1, then both errors are detected by the receiver. Thus, choosing an appropriate divisor is crucial in detecting errors at the receiver if any during the transmission.

CODE DESIGN

I have implement the the solution using three program files namely as:
Sender.py:this program runs as a sender node.
Receiver.py: this program runs as a receiver node.
Runner.py: this program acts as the interface between the sender ans receiver.

```
Runner.py
Functions:
insertRandomError():
insertSpecficError():
generateRandomInput():
case1():
Case2():
case3():
```

sender.py	receiver.py
Codeword: dataSize: Parity: checkSum: Functions: createFrames(): displayFrames(): rowParityGenerator(): coloumParityGenerator(): add(): calculateSum(): xor(): divide():	codeWord: dataSize: sentParity: Recivedparity: sentCheckSum: Sum: addChecksum: Complement: Functions: checkError(): displayFrames(): add(): calculateSum(): xor(): divide():

sender.py – The following are the tasks performed in this Sender program :

1. The sequence of 0's ans 1's are read from input file.
2. This sequence is divided into datawords on the basis of frame size taken as the input from the user.
3. According to the four schemes namely VRC, LRC, Checksum and CRC, redundant bits/dataword are added along with the datawords to form codewords.
4. The datawords and codewords which are to be sent are displayed.
5. These encoded codewords are then sent to the receiver.

receiver.py – The following are the tasks performed in this Receiver program :

1. The codewords are received from the sender.

2. The received codewords are then decoded according to the four schemes namely VRC, LRC, Checksum and CRC.

3. The result is checked and shown if there is any error detected.

4. The codewords and the datawords extracted from the codewords are also displayed.

run.py – The following are the tasks performed in this program :

1. This program acts as an interface to the above programs – sender.py and receiver.py
2. In this program, the functions for injecting errors are included.
3. There are two separate functions for injecting errors on random positions of codeword, and for injecting errors on specific positions taken as input.
4. A filename is taken as input from command line while executing the program.
5. This is then used as the input file which has a sequence of 0 and 1 stored in it. The function invocations of Sender class stored in sender.py and Receiver class stored in receiver.py are done in this file to send and receive the data.
6. The sent data are injected with errors using the above mentioned functions.For all the following three cases, three different functions have been created to execute a specific case at a moment.

   i. Error is detected by all four scheme

   ii. Error is detected by checksum but not CRC.

   iii. Error is detected by VRC but not CRC.

IMPLEMENTATION

Code for sender.py

```python
class Sender:
  #Initialize all the data members of class
  def __init__(self, size):
      self.codeword = []
      self.dataSize = size
      self.parity = ""
      self.checksum = ""

  #Function to generate codewords to be sent
  def createFrames(self, filename, type, poly=""):
      fileinput = open(filename, "r")
      packet = fileinput.readline()
      fileinput.close()
      tempword = ""

      if type == 1:
          for i in range(len(packet)):
              if i>0 and i%self.dataSize==0:
                  self.codeword.append(tempword)
                  tempword = ""
              tempword += packet[i]
          self.codeword.append(tempword)
          self.rowEvenParityGenerator()

      elif type == 2:
          for i in range(len(packet)):
              if i>0 and i%self.dataSize==0:
                  self.codeword.append(tempword)
                  tempword = ""
              tempword += packet[i]
```

```python
            self.codeword.append(tempword)
            self.columnEvenParityGenerator()

    elif type == 3:
        for i in range(len(packet)):
            if i>0 and i%self.dataSize==0:
                self.codeword.append(tempword)
                tempword = ""
            tempword += packet[i]
        self.codeword.append(tempword)

        summ = self.calculateSum()
        for i in range(len(summ)):
            if summ[i]=='0':
                self.checksum += '1'
            else:
                self.checksum += '0'

    elif type == 4:
        tempsize = self.dataSize #- (len(poly)-1)
        for i in range(len(packet)):
            if i>0 and i%tempsize==0:
                tempword += '0'*(len(poly)-1)
                remainder = self.divide(tempword, poly)
                remainder = remainder[len(remainder)-(len(poly)-1):]
                tempword = tempword[:tempsize]
                tempword += remainder
                self.codeword.append(tempword)
                tempword = ""
            tempword += packet[i]

        tempword += '0'*(len(poly)-1)
        remainder = self.divide(tempword, poly)
        remainder = remainder[len(remainder)-(len(poly)-1):]
        tempword = tempword[:tempsize]
        tempword += remainder
```

```python
            self.codeword.append(tempword)

#Function to display the sent codewords

    def displayFrames(self, type):
        datawords = []
        for x in self.codeword:
            datawords.append(x[:self.dataSize])

        print("_____")
        print("_____Datawords to be sent:_____")
        print("_____")
        print(datawords)
        print("Codewords sent by sender:")
        print(self.codeword)
        if type == 2:
            print(self.parity, " - parity")
        elif type == 3:
            print(self.checksum, " - checksum")
        print("\n")

#Helper function for VRC Even Parity generator

    def rowEvenParityGenerator(self):
        for i in range(len(self.codeword)):
            countOnes = 0
            for j in range(len(self.codeword[i])):
                if self.codeword[i][j] == '1':
                    countOnes += 1
            if countOnes%2==1:

            else:
                self.codeword[i] += '0'

#Helper function for LRC Even Parity generator
```

```python
def columnEvenParityGenerator(self):
    i=0
    while i<self.dataSize:
        countOnes = 0
        j=0
        while j<len(self.codeword):
            if self.codeword[j][i] == '1':
                countOnes += 1
            j+=1
        if countOnes%2==1:
            self.parity += '1'
        else:
            self.parity += '0'
        i+=1

#Helper function to add two binary sequence
def add(self, a, b):
    result = ""
    s = 0
    i = len(a)-1
    j = len(b)-1
    while i>=0 or j>=0 or s==1:
        if i>=0:
            s+=int(a[i])
        if j>=0:
            s+=int(b[j])
        result = str(s%2) + result
        s //= 2
        i-=1
        j-=1
    return result

#Helper function to calculate sum of all codewords
def calculateSum(self):
    result = self.codeword[0]
    for i in range(1,len(self.codeword)):
        result = self.add(result, self.codeword[i])
```

```python
            while len(result) > self.dataSize:
                t1 = result[:len(result)-self.dataSize]
                t2 = result[len(result)-self.dataSize:]
                result = self.add(t1, t2)
        return result

    #Helper function to XOR two binary sequence
    def xor(self, a, b):
        result = ""
        for i in range(1, len(b)):
            if a[i]==b[i]:
                result += '0'
            else:
                result += '1'
        return result

    #Helper function to divide two binary sequence
    def divide(self, dividend, divisor):
        xorlen = len(divisor)
        temp = dividend[:xorlen]
        while len(dividend) > xorlen:
            if temp[0]=='1':
                temp=self.xor(divisor,temp)+dividend[xorlen]
            else:
                temp=self.xor('0'*xorlen,temp)+dividend[xorlen]
            xorlen += 1
        if temp[0]=='1':
            temp=self.xor(divisor,temp)
        else:
            temp=self.xor('0'*xorlen,temp)
        return temp
```

ANALYSIS OF SENDER.PY

createFrames(self,filename,type,poly=""):
We take input as the filename type(type of technique) and the polynomial if it is CRC.
Here we read the entire sequence of 0's ans 1's form the file and then divide the
sequence into data frames of the required length that is also given by the user.
After dividing into frames we append each message with the redundant bits receptive to
the type of error technique;

displayFrames(self):
This method simply displays the frames with the corresponding redundant bits on
console.

rowEvenParaityGenerator(self):
This method is used to generate paraty in case of VRC.

coloumEvenParaityGenerator(self):
This method is used to generate paraty in case of LRC.

add(self,a,b):
This method has been used as a helper function for implementing Checksum. It takes
two binary sequence as parameters, and returns the result of wrapped addition of them.

calculateSum(self) :
This method has been used as a helper function for implementing Checksum. It
calculates the sum of all the datawords (using the above mentioned function) and
returns the result.

xor(self,a,b) :
This method has been used as a helper function for implementing CRC. In this method,
two binary sequence is taken as input from its arguments, and return the xor of them.

divide(self,dividend,divisor) :
This method has been used as a helper function for implementing CRC. In this method,
dividend and divisor is taken as input from its arguments. The division is performed
using mod 2 arithmetic (exclusice-OR) on the message using divisor polynomial, and
the remainder is returned.

Code for receiver.py

```python
class Receiver:
    #Initialize all the data members of class
    def __init__(self, s):
        self.codeword = s.codeword
        self.dataSize = s.dataSize
        self.sentparity = s.parity
        self.receivedparity = ""
        self.sentchecksum = s.checksum
        self.sum = ""
        self.addchecksum = ""
        self.complement = ""

    #Function to decode and check for error in codewords
    def checkError(self, type, poly=""):

        if type == 1:
            for i in range(len(self.codeword)):
                countOnes = 0
                for j in range(len(self.codeword[i])):
                    if self.codeword[i][j]=='1':
                        countOnes += 1
                if countOnes%2==0:
                    print("the Parity of recived packet is even.", end=' ')
                    print("NO ERROR DETECTED")
                else:
                    print("the Parity of recived packet is odd.", end=' ')
                    print("ERROR DETECTED")

        elif type == 2:
            error = False
```

```python
        i=0
        while i<self.dataSize:
            countOnes = 0
            j=0
            while j<len(self.codeword):
                if self.codeword[j][i] == '1':
                    countOnes += 1
                j+=1

ANALYSIS OF SENDER.PY

checkError(self,type,poly="") :
This method takes type (scheme) of error detection method as one of its argument. On the basis of the scheme the codewords received is checked for error. If there is an error, appropriate message is displayed on the screen.

displayFrames(self,type) : This method has been used to display the received codewords and datawords from the sender.

add(self,a,b) :
This method has been used as a helper function for implementing Checksum. It takes two binary sequence as parameters, and returns the result of wrapped addition of them.

calculateSum(self) :
This method has been used as a helper function for implementing Checksum. It calculates the sum of all the datawords (using the above mentioned function) and returns the result.

xor(self,a,b) :
This method has been used as a helper function for implementing CRC. In this method, two binary sequence is taken as input from its arguments, and return the xor of them.

divide(self,dividend,divisor) :

This method has been used as a helper function for implementing CRC. In this method, dividend and divisor is taken as input from its arguments. The division is performed using mod 2 arithmetic (exclusice-OR) on the message using divisor polynomial, and the remainder is returned.

ANALYSIS OF RUNNER.PY

generateRandomInput(filename,size):this methos generates 1 or 0 in random manner and saves them into file given by filename util it number of bits reach to size.

inputRandomError(frames) : This method is used to inject errors in random positions of the codewords which are sent by sender program. The randint() function of random python module has been used for generating random position within the size of the codewords.

inputSpecificError(frames,zeropos,onepos) : This method is used to inject errors in specific positions of the codewords. The positions in which the error is to be inserted is passed as arguments, as zeropos and onepos. Zeropos contains the list of positions in which the value of those positions will be made 0, whereas Onepos containes the list of positions in which the value of those positions will be made 1.

case1(size,filename) : This method is implemented to make function invocations and displaying the results of all schemes, considering the case 1 of the problem statement (Error is detected by all four schemes). The dataword size and input file name is taken as function arguments.

case2(size,filename) : This method is implemented to make function invocations and displaying the results of Checksum and CRC, such that the case 2 of the problem statement satisfies (Error is detected by Checksum but not CRC). The dataword size and input file name is taken as function arguments.

case3(size,filename) : This method is implemented to make function invocations and displaying the results of VRC and CRC, such that the case 3 of the problem statement satisfies (Error is detected by VRC but not CRC). The dataword size and input file name is taken as function arguments.

Output for case 1: Error is detected by all four schemes. Use a suitable CRC polynomial.

COMMENTS

- This assignment helped me to understand various error detection techniques used in data communication.
- This assignment also helped me to implement that understanding into a real life program that could be used to detect those errors in any data communication model .
